11   Abstract

12   De Freitas and Johnson (2018) found that people are blamed for making suboptimal

13   decisions, even under circumstances in which an optimal decision cannot reasonably be

14   expected (De Freitas & Johnson, 2018). They termed this phenomenon "optimality bias,"

15   and stated that it depended only on a reference to the relevant agents' choices, making no

16   reference to their mental states. More precisely, they stated that suboptimal decisions are

17   seen as more difficult to explain and are, therefore, also perceived to be more deserving of

18   blame. However, what if the cause of this bias is instead an overassessment of the decision

19   makers' abilities (thus, making reference to their mental states)? In a series of three

20   studies, we examined whether thinking that an agent "should have known better" predicts

21   blame judgments better than thinking an explanation was needed for their suboptimal

22   behavior, as well as whether this effect is only found when judging experts. From our first

23   study, we discovered that the sentiment that an agent "should have known better" explains

24   optimality bias better than De Freitas and Johnson's proposed explanation. From our

25   second study, we found evidence that expertise affects the potency of optimality bias, which

26   again opposes De Freitas and Johnson's non-mentalistic explanation for the bias. And from

27   our third study, we found evidence that eliminating an agent's potential to acquire greater

28   knowledge impacted optimality bias—a finding which we replicated in a follow-up

29   study—providing further support for our more mentalistic explanation for the bias.

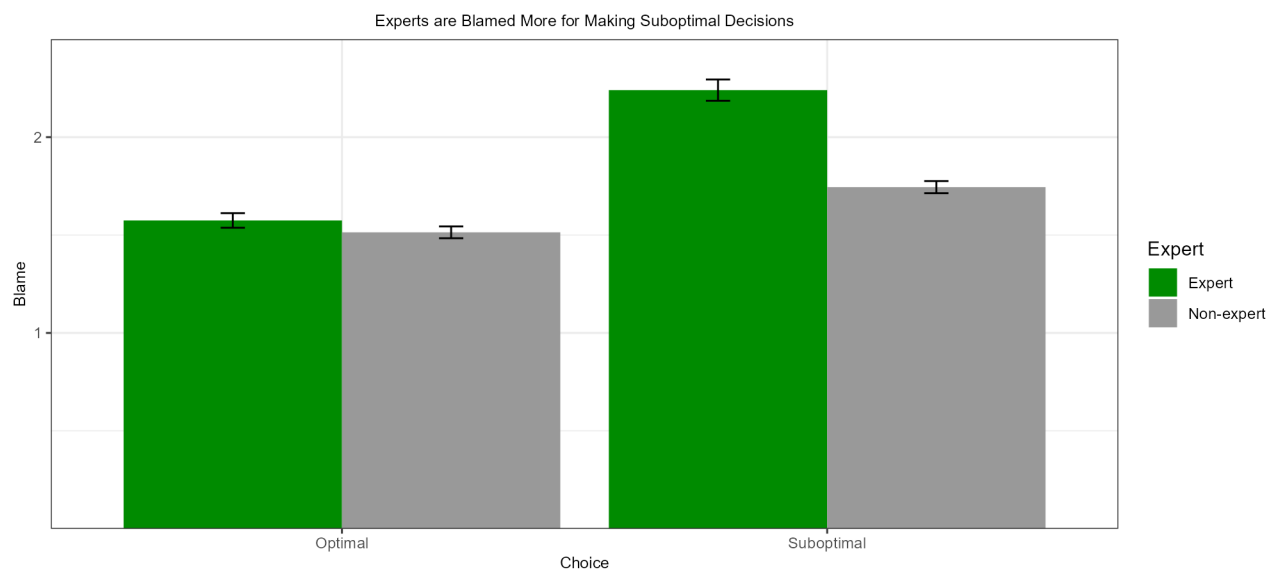

Figure 2. This is a smaller bar chart.

Introduction

On January 21, when the first case of COVID-19 in the United States was confirmed, Dr. Anthony Fauci, the Chief Medical Advisor to the President of the United States, stated, "[COVID-19] is not a major threat to the people of the United States, and this is not something that the citizens of the United States right now should be worried about" (A. Fauci, Interview on Newsmax TV, Jan. 21, 2020). Unfortunately, one case would soon turn to one hundred; then a thousand; there have now been 80.5 million reported cases in the United States since the first case (CDC, 2022). Fauci was condemned for his inaccurate predictions about the virus (see for instance, "How Fauci Fooled America", Kulldorff & Bhattacharya, 2021), but he was not alone. Infectious disease experts have been widely criticized for their mistaken beliefs about COVID-19, especially concerning their health advice. Not long after COVID-19 cases first began to surge, articles titled such things as: "Shocker! The Experts Were Wrong" (Greenhut, 2020), and "Erosion of trust: 10 things

⁴⁶ public health establishment got wrong about coronavirus" (Fumento, 2020) started

⁴⁷ appearing across the Internet. Criticism of this sort is not limited to the field of infectious

⁴⁸ disease, however. In 2009, Italian seismologists were charged with manslaughter, and

⁴⁹ sentenced to six years in prison, for failing to predict an earthquake in the city of L'Aquila

⁵⁰ that killed 308 people (Pappas, 2012). Although this conviction was overturned on appeal,

⁵¹ this incident set a disturbing precedent for scientists and other experts who might wish to

⁵² offer advice to the public in the future. In this case, although the seismologists were

⁵³ well-informed, and based their opinion on the existing evidence, they turned out to be

⁵⁴ wrong, and were therefore blamed harshly as a consequence (see De Freitas & Johnson,

⁵⁵ 2018).

⁵⁶   This pattern may in part reflect the well-known phenomenon of outcome bias,

⁵⁷ according to which, people judge the quality of a decision by its outcome (Baron &

⁵⁸ Hershey, 1988). In each of the cases above, the outcome was bad, and so the decision itself

⁵⁹ is judged as correspondingly bad. However, there may be another dynamic underlying

⁶⁰ people's negative reactions to these cases as well. According to De Freitas and Johnson

⁶¹ (2018), people may also focus on the suboptimality of the agents' choices in these cases –

⁶² that is, the fact that their choices do not correspond to the choices that would have been

⁶³ made by an omniscient agent. In their analysis of the L'Aquila episode, De Freitas and

⁶⁴ Johnson argue that:

⁶⁵   "Not only did the scientists' choice result in a bad outcome, but, unknown to the

⁶⁶ scientists, it was also suboptimal. That is, even before the earthquake itself, an omniscient

⁶⁷ scientist could have known that the earthquake was likely to occur. Thus, the optimal

⁶⁸ choice would objectively have been to recommend evacuation." (p. 149).

⁶⁹   If people do indeed blame actors for making suboptimal choices even when they could

⁷⁰ not reasonably have known better, this would indicate their susceptibility to a novel

⁷¹ "optimality bias" that represents the inverse of outcome bias. Whereas outcome bias

⁷² captures cases in which individuals who make identical choices are blamed differently

73 depending on the outcome of their decision (e.g., imagine that the earthquake in L'Aquila

74 did not occur), optimality bias captures cases in which individuals make equally

75 well-informed choices that lead to identical outcomes, and yet are blamed in accordance

76 with whether their choices are optimal given omniscient knowledge of the situation that

77 was unavailable at the time of decision (De Freitas & Johnson, 2018).

78   Consider the following sort of case, which De Freitas and Johnson (2018) developed

79 to examine this bias experimentally. A doctor must decide between three options for a

80 patient suffering from hearing problems. The existing evidence indicates that all three

81 choices should yield a 70% chance of recovery. The doctor believes this and chooses one of

82 the treatments on this basis. But the evidence is misleading. In fact, only one of the three

83 options (best) yields a 70% chance of recovery. The middle (50%) and worst (30%) options

84 yield lower chances of recovery. In a between-subjects design, De Freitas and Johnson

85 manipulated which option the doctor chose (and similarly for other agents in analogous

86 vignettes). In each case, a negative outcome – no recovery from hearing loss – ensued. And

87 yet, even in cases in which it was noted that the doctor based her decision on all of the

88 existing evidence, she was blamed more when she made either one of the suboptimal

89 choices (50% or 30%), as compared with the optimal choice (70%), and there was typically

90 little differentiation between the two suboptimal choices themselves.

91   De Freitas and Johnson's discovery of this intriguing bias was accompanied by a

92 rather startling explanation. They argued that the optimality bias occurs because of the

93 efficiency principle, according to which people expect others to behave efficiently (i.e.,

94 optimally) in any given situation, regardless of their mental states (Dennett, 1987; Gergely

95 & Csibra, 2003). Under this principle, decision-makers are purported to "rely on states of

96 the world to assign blame and may even do so by overriding or ignoring an agent's mental

97 states" (p. 160). This pattern, "can be considered a form of moral behaviorism, in that

98 people bypass the agent's mental states to assess blame" (p. 160). In other words, if an

99 agent's choice is suboptimal, it warrants blame for that reason alone. There is no need to

consider what the agent did know, could have known, or should have known in making the choice. De Freitas and Johnson (2018) argued that the reason why people blame suboptimal choices is that such choices violate their expectations. Any choice that is suboptimal is capable of provoking this sense of expectation violation. Hence, according to De Freitas and Johnson, one advantage of this account is that it readily makes sense of the relative lack of differentiation between the middle and worst choices – both choices violate expectations by being suboptimal, and so there is no further need to distinguish them. They presented additional mediation evidence supporting this account. They also presented evidence suggesting that the bias was not moderated by mental state variables, such as the agent's negligence or their presumed tacit knowledge. However, both of these findings warrant further scrutiny, as we argue below. In sum, De Freitas and Johnson (2018) discovered an important and novel phenomenon, documented it comprehensively across seven studies, and offered a provocative explanation for it. In the present paper, our main focus is to replicate the bias, question this explanation, and examine an alternative explanation.

De Freitas and Johnson's (2018) explanation is especially provocative in virtue of its discounting of mental state reasoning. As much research in moral psychology has documented, people typically do integrate mental state considerations when apportioning blame, chiefly intentionality, reasons (or motives), and negligence (for a review, see Malle, 2021). For instance, on the Path Model of Blame, when someone causes a bad outcome, people principally consider that person's intentions (Malle, Guglielmo, & Monroe, 2014). When an agent caused a bad outcome intentionally, people subsequently consider their reasons for acting, and apportion blame in accordance with the culpability of those reasons. When the agent caused the outcome unintentionally, people consider their capacity and obligations to prevent that outcome from occurring – in other words, they consider whether the agent acted negligently – and apportion blame accordingly.

Given this intense focus on mental states, it would seem quite surprising if people

discounted them entirely when judging blame for suboptimal choices. Indeed, we suspected that mental states would figure quite prominently in the true explanation of optimality bias, in the following way: When people learn that an agent, especially an expert, made a suboptimal choice, they question whether or not the agent could or should have known better in making their choice. Was there perhaps some way in which the agent could have acquired greater knowledge that would have enabled them to choose more optimally? And if so, should the agent have taken steps to acquire such knowledge? If the answer to these capacity and obligations questions is yes, then increased blame attributions should ensue.

This mental-state-based account makes several predictions that differentiate it from De Freitas and Johnson's (2018) explanation. First, it predicts that accurate measures of negligence and other mental state reasoning should mediate the optimality bias. Second, it predicts that the optimality bias should be exacerbated when an agent's capacity and obligation to prevent negative outcomes are enhanced. And third, it predicts that the optimality bias should recede and possibly vanish when an agent's capacity and obligation to prevent negative outcomes are completely eliminated (for instance, when they make a choice in total ignorance of which option they are choosing in the first place).

Furthermore, this explanation is not sufficiently ruled out in De Freitas and Johnson's (2018) otherwise exemplary studies. The possibility that negligence might interact with optimality bias was examined in only one study, and the measure used, presented below was arguably too indirect:

"While answering the question about blame, did you think that if the doctor had thought more carefully or done more research, then she would have been able to know which options were better and which were worse?"

One problem with this question is that it asks retrospectively for a report on the participant's cognitive processes, rather than for a more direct assessment of the facts of the case. Second, this question does not adequately diagnose negligence, because it invites an affirmative answer even in the case in which the doctor did make the optimal decision.

If the doctor could have gained more knowledge in the worst or middle condition, then she presumably could similarly have gained that knowledge even in the best condition as well. Additionally, even if the doctor in the best condition already knew which options were better and which were worse, it would still be correct to give an affirmative answer, indicating that agreement with this statement does not necessitate any attribution of negligence. What matters in diagnosing negligence is whether this knowledge would have changed her choice. Accordingly, a more telling question regarding capacity would ask whether more thinking or more research would have changed the doctor's decision. Finally, this question represents an incomplete assessment of negligence because it asks about only about the doctor's capacity, and not her obligation to think or research more carefully. In other words, it only queries whether the doctor could have gained more knowledge, not whether she should have. And this obligation to obtain more accurate knowledge also arguably differs across the three conditions – being more pronounced in the cases in which suboptimal choices were made. Only with a more direct measure of obligation can the role of negligence be assessed comprehensively[1].

Another problem with the existing process evidence concerns De Freitas and Johnson's (2018) "need for explanation" measure, which was worded as follows: "To what extent do you feel that an explanation is necessary for the doctor's choice?" This measure is supposed to measure the surprisingness or unexpectedness of the agent's choice, which is thought to be the key mediating variable on the moral behaviorist theory. While it clearly does capture this to some degree, it can also be read as a demand for accountability – that is, to what extent should the doctor be called to account for their choice? Clearly this demand should be higher if the doctor made a suboptimal choice – it is natural to expect greater scrutiny of the doctor's decision-making in this case. In other words, this measure does not merely capture the unexpectedness of the doctor's choice, it also captures

---

[1] It would also be desirable to test whether improved measures of negligence mediate the optimality bias, not merely whether they moderate the bias. De Freitas and Johnson (2018) tested moderation only.

something about the wrongness or blameworthiness of the doctor's choice. In this sense, ironically, it is arguably closer to being a measure of negligence, meaning that its apparent explanatory power may be misidentified in De Freitas and Johnson's work. In order to measure expectation violation in the terms of De Freitas and Johnson's theory, a more neutral measure which queries only the unexpectedness of the doctor's choice is needed. We attempted such a measure in the studies below. One objection that might be registered against this line of reasoning is that the possibility of the agents attaining greater knowledge was ruled out by a stipulation in De Freitas and Johnson's (2018) vignettes. For instance, in Study 2, which was the most tightly controlled study in this respect, participants read the following passage: "Based on many articles that the doctor has carefully read in respected medical journals, she truly believes that all three options have an 80% chance of giving the patient a full, successful recovery. In fact, all of the existing evidence says that this belief is correct. But as it happens, for reasons completely outside of her control, the doctor's belief is wrong" (p. 153).

At first blush, this passage does seem to preclude the possibility of the doctor's obtaining more accurate information about the respective treatments' chances of success. However, the key question is whether the participants themselves saw things this way. Might some participants have believed that if the doctor had engaged in more thorough research, deeper thinking, or had superior clinical intuition or instinct, they could have ended up in a superior epistemic position? If so, then they would effectively be overriding the stipulation by reasoning about the actor's mental states and capacities. Supporting this possibility, some research has indeed documented that participants do not always accept information stipulated by the experimenter in moral judgment contexts. For instance, Royzman, Kim, and Leeman (2015) showed that participants tend not to believe an experimenter stipulation that sibling incest is completely harmless. Without direct investigation, it seems unclear whether participants did or did not accept the stipulation in the present case that improved knowledge was impossible.

₂₀₆ In sum, the discovery of the optimality bias is an important recent contribution, but

₂₀₇ its explanation by De Freitas and Johnson (2018) is not entirely convincing. In the four

₂₀₈ studies that follow, we aimed first to replicate the optimality bias, and subsequently, to

₂₀₉ examine both De Freitas and Johnson's behaviorist explanation using revised measures, as

₂₁₀ well as our own mentalistic explanation, using novel measures.

₂₁₁ In Study 1, we examined whether participants believe that the agent not only could

₂₁₂ have known better, but should have known better; that is, that the agent had both the

₂₁₃ capacity and the obligation to obtain more accurate knowledge of the situation. If

₂₁₄ participants endorse this belief, then this would support a mentalistic account of optimality

₂₁₅ bias, predicated on an attribution of negligence. In Study 2, we examined whether

₂₁₆ optimality bias is stronger for experts than non-experts. Experts have a superior ability to

₂₁₇ acquire knowledge compared to non-experts, and should therefore be held to a higher

₂₁₈ standard for failing to have accurate knowledge. Thus, according to the mentalistic

₂₁₉ explanation, the optimality bias should be stronger for experts than non-experts, whereas

₂₂₀ this variable should make no difference according to De Freitas and Johnson's (2018)

₂₂₁ behaviorist explanation. By experimentally manipulating expertise, which reflects a mental

₂₂₂ capacity variable, Study 2 provides a critical test of the mentalistic explanation. In Studies

₂₂₃ 3a and 3b, we examined whether optimality bias is stronger when agents know which

₂₂₄ option they are selecting, as compared with when they do not know which option they are

₂₂₅ selecting, and are instead choosing completely "blindly." If a choice is made in total

₂₂₆ ignorance of what option is being selected, then the possibility of obtaining improved

₂₂₇ knowledge of the properties of the different options should not matter whatsoever, and

₂₂₈ according to the mentalistic explanation, the optimality bias should disappear. In contrast,

₂₂₉ the behaviorist explanation predicts that this variable should also make no difference; all

₂₃₀ that matters is whether or not the choice was optimal. In each of these studies, we also

₂₃₁ measured De Freitas and Johnson's (2018) need for explanation construct to examine how

₂₃₂ well it accounts for the optimality bias compared to our negligence construct.

₂₃₃ **Methods**

₂₃₄   Study 2 manipulated the expertise of the decision-maker in order to determine

₂₃₅ whether a mentalistic or behaviorist explanation for optimality bias was more accurate.

₂₃₆ According to our mentalistic explanation, optimality bias should be stronger for experts

₂₃₇ than non-experts since experts are expected to have a greater ability to acquire critical

₂₃₈ knowledge. They should therefore be held to greater account when they fail to have such

₂₃₉ knowledge. According to De Freitas and Johnson's behaviorist explanation, however, the

₂₄₀ bias should be equally evident for experts and non-experts, since on this account, blame

₂₄₁ depends only on the (sub)optimality of a given choice, not differential cognitive abilities. In

₂₄₂ addition to testing this moderation hypothesis, we also tested mediation by once again

₂₄₃ measuring perceptions of negligence and need for explanation.

₂₄₄ **Participants**

₂₄₅   We recruited 1003 participants (524 reported female; $M_{age} = 33.6$, $SD = \neg\ 12.21$), all

₂₄₆ of whom resided within the United States, from Prolific Academic. For this study, we used

₂₄₇ two new vignettes ("Island" and "Ship"). In accordance with the preregistration, a total of

₂₄₈ 315 participants had their data excluded for at least one of the vignettes due to their

₂₄₉ failing the comprehension check for the associated vignette(s). 136 participants failed both

₂₅₀ of the vignettes' comprehension checks; 93 participants failed only the comprehension check

₂₅₁ for "Island"; and 86 failed only the comprehension check for "Ship." Thus, the final sample

₂₅₂ for the primary analysis below consisted of 688 participants since this analysis required

₂₅₃ participants to have data for both vignettes. Our subsidiary analyses on the individual

₂₅₄ vignettes did not have this same requirement – for these analyses, complete data was

₂₅₅ required only for the vignette being analyzed. The samples for these analyses consisted of

₂₅₆ 774 participants (for "Island") and 781 participants (for "Ship").

Design, Materials, and Procedure

The two new vignettes ("Island" and "Ship") were presented to all participants in a randomized order. Participants were randomly assigned to one of four between-subjects conditions, based on the choice the agent made in each of the vignettes (optimal vs. suboptimal), and whether the agent was an expert or non-expert (these two variables remained constant across the two vignettes each individual participant received). As compared with Study 1, there were only two options, an optimal choice with a 70% chance of success, and a single suboptimal choice with a 50% chance of success. However, as before, the agents made their choices in ignorance of the true probabilities of success – in each case, they falsely believed that the probabilities of success for each choice were equivalent (at 70%). Lastly, as before, the outcome of the agent's decision was always unsuccessful.

Both of the new vignettes were designed to control for factors that would prevent a proper comparison between experts and non-experts (see Appendix A.2 for the full text of these vignettes). For instance, each vignette was set in isolated and time-urgent circumstances so as to prevent the agents from receiving external assistance in making their decision. Access to such external resources would diminish the utility of the comparison between experts and non-experts (since both experts and non-experts alike could avail themselves of such external assistance). All names used in the vignettes were matched so that they had similar warmth and competence (Newman et al., 2018). The complete text of the Island vignette (expert condition) is presented below:

Samantha and Bailey, strangers to each other, both win an island getaway where they will spend a week completely isolated from civilization, with no phone or internet connection, just the two of them. Unfortunately, just a few days into their stay, Bailey is bitten by a venomous snake and falls seriously ill. Samantha knows that she will have to find an antidote in their packed first aid kit to treat Bailey's condition. Samantha finds two antidotes in the kit, but the labels have been partially torn off, so they only show the medical terms for each antidote: LPN and PTY. Samantha, being a doctor, bases her

decision on many articles that she has carefully read in respected medical journals across

the years. Based on this evidence, she believes that both antidotes have an equal chance of

allowing Bailey to recover fully. In fact, all of the existing evidence in the medical journals

supports this belief. But as it happens, for reasons completely outside of her control,

Samantha's belief is wrong. Actually:

1) If antidote LPN is administered, there is a 70% chance that Bailey will have a full
recovery.

2) If antidote PTY is administered, there is a 50% chance that Bailey will have a full
recovery.

Samantha remembers from her medical training that she can only administer one of

the antidotes since administering both would render them ineffective. She chooses to

administer antidote [LPN/PTY], and Bailey does not recover. Bailey ends up dying from

the snakebite.

Participants first viewed one of the vignettes at random and then responded to

questions gauging the agent's negligence and the need for explanation construct. To

measure negligence, we retained two measures from Study 1 ("Should the [agent] have

known better in making the choice that [he/she] did?"; "If the [agent] had thought more

carefully about her decision, would it have changed the decision [he/she] ultimately

made?"). We excluded one measure ("If the [agent] had been able to do more research,

would it have changed the decision [he/she] ultimately made?") because, in the context of

the vignettes, the inability to do further research was integral to the circumstances

described; failure to do further research was therefore not a measure of negligence. For the

"need for explanation" construct, we retained only the single measure that best captured

De Freitas and Johnson's (2018) interpretation of the construct (namely: "To what extent

do you understand why the [agent] made the choice that [he/she] did?", see earlier).

Participants then answered two questions about the agent's deserved blame, which were

light modifications of the blame measure from our first study. These measures, which can

311   be found in Appendix B.2, were formulated to differentiate between blame for the agent's

312   choice, and blame for the negative outcome that ensued. Next, on a separate page,

313   participants answered two comprehension check questions (see earlier for exclusion

314   criteria). Participants repeated this process for the second of their two vignettes. All

315   measures included numerical scale values since we no longer felt it necessary to precisely

316   emulate De Freitas and Johnson's original study materials.

317   Finally, after completing the measures for each vignette, on a separate page,

318   participants judged the agents' expertise (e.g., "In the vignette, to what extent was [agent]

319   a [medical/fish] expert?") for each vignette they received. This functioned as a

320   manipulation check to ensure experts' and non-experts' perceived expertise was different

321   from one another. Participants then completed a series of standard demographic measures.

Data analysis
322

323   The aggregated negligence (island vignette, $p = 0.92$; ship vignette $p = 0.91$) and

324   blame items (island vignette, $p = 0.82$; ship vignette $p = 0.77$) were highly reliable, and so

325   both were collapsed into composite measures. Our manipulation of the expertise of the

326   agents was successful – the expert was rated as having greater expertise in both the

327   "Island" ($M = 7.80$, $SD = 1.60$) and "Ship" ($M = 7.76$, $SD = 1.75$) vignettes compared to

328   the non-expert (MIsland $= 1.49$, $SD = 1.31$; MShip $= 1.57$, $SD = 1.33$), ps < 0.001.

329   In accordance with the preregistration, we ran a mixed-model measures analysis to

330   determine the differences in mean blame ratings as a function of choice, expertise, and

331   vignette, as well as the two- and three-way interactions. We observed a main effect of

332   choice on these blame ratings, such that those who made the optimal decision ($M = 1.62$,

333   $SD = 1.22$) were blamed less than those who made the suboptimal one ($M = 2.01$, $SD =$

334   1.48), $F(1, 684) = 21.96$, $p < 0.001$, $n_p^2 = 0.031$). There was also an effect of expertise on

335   blame ratings, indicating that experts ($M = 1.98$, $SD = 1.62$) were generally blamed more

336   than non-experts ($M = 1.68$, $SD = 1.07$), $F(1, 684) = 8.45$, $p = 0.004$, $n_p^2 = 0.012$. There

337 was also an overall effect of vignette, indicating that blame was slightly higher for the Ship

338 case ($M = 1.83$, $SD = 1.38$) than for the Island case ($M = 1.73$, $SD = 1.34$), $F(1, 684) =$

339 8.26, $p = 0.004$, $n_p^2 = 0.012$.

340   Most importantly, we observed the predicted interaction between choice and

341 expertise, indicating that the optimality bias was stronger for experts than non-experts,

342 $F(1, 684) = 5.17$, $p = 0.023$, $n_p^2 = 0.007$ (see Figure 1 for a visualization of this interaction).

343 However, the optimality bias was not eliminated for non-experts, it was simply diminished.

344 For experts, participants assigned lesser blame to agents who made the optimal decision

345 ($M = 1.57$, $SD = 1.18$) compared to those who made the suboptimal decision ($M = 2.24$,

346 $SD = 1.72$), $F(1, 684) = 23.84$, $p < 0.001$, $n_p^2 = 0.034$. For non-experts, participants

347 assigned lesser blame to agents who made the optimal decision ($M = 1.51$, $SD = 0.96$)

348 compared to those who made the suboptimal decision ($M = 1.74$, $SD = 0.98$), but the

349 difference was not significant, and the effect size was 8.5 times smaller than it was for

350 experts, $F(1, 684) = 2.96$, $p = 0.086$, $n_p^2 = 0.004$. There were no other significant two- or

351 three-way interactions (see Table 1 for descriptive statistics). We next conducted analyses

352 on each of the individual vignettes. These analyses included all participants who passed

353 the comprehension check for the respective vignette, so the samples are larger than those

354 reported in the main analyses above. For brevity, we report here only the key results, with

355 full results presented in the Supplemental Materials. For the island vignette, the

356 interactive effect of choice and expertise on blame was highly significant, $F(1, 770) =$

357 10.62, $p = 0.001$, $n_p^2 = 0.014$. The optimality bias was present for experts, who were

358 blamed more when they made the suboptimal choice ($M = 2.32$, $SD = 1.88$) as compared

359 with the optimal choice ($M = 1.51$, $SD = 1.17$), $F(1, 770) = 31.00$, $p < 0.001$, $n_p^2 = 0.039$;

360 but it was not present for non-experts, for whom this difference was insignificant ($M_{50} =$

361 1.81, $SD = 1.21$ vs. $M_{70} = 1.67$, $SD = 1.33$), $F(1, 770) = 0.997$, $p = 0.32$, $n_p^2 = 0.001$).

362   For the ship vignette, the interaction of choice and expertise on blame was not

363 significant, $F(1, 777) = 2.24$, $p = 0.135$, $n_p^2 = 0.003$. Although this interaction was not

significant, we once again observed that the optimality bias was present for experts ($M_{50} =$ 2.29, $SD = 1.78$ vs. $M_{70} = 1.80$, $SD = 1.53$), $F(1, 770) = 11.82$, $p < 0.001$, $n_p^2 = 0.015$, but not for non-experts ($M_{50} = 1.80$, $SD = 1.14$ vs. $M_{70} = 1.61$, $SD = 1.10$), $F(1, 770) = 1.84$, $p = 0.175$, $n_p^2 = 0.002$.

Finally, we conducted several exploratory mediation analyses. For Studies 2, 3a, and 3b, we had originally preregistered running mediated moderation analyses of the overall interaction patterns. However, we later became convinced that these analyses were not as diagnostic as we had originally thought (see e.g., Edwards, 2009, pp. 156-157; Hayes, 2021, pp. 487-489). Accordingly, for each of these studies, we now report exploratory simple and parallel mediation models in only the condition in which we expected the optimality bias to occur (and not the experimental conditions in which we expected it to be diminished or eliminated). Although these analyses were not preregistered, their structure is identical across Studies 2, 3a, and 3b. We report the originally preregistered analyses in the Supplemental Materials.

For Study 2, we examined several simple and parallel mediation models in just the expert condition since this condition best captured the optimality bias. When both vignettes were combined, there was a significant indirect effect of negligence when entered as the sole mediator (a path = -0.81, $p < 0.001$; b path = 0.66, $p < 0.001$, ab path = -0.53, CI = -0.80 to -0.29; based on 5,000 bootstrap samples, Hayes PROCESS macro, Model 4), and a significant effect of need for explanation when it was entered alone (a path = 0.84, $p < 0.001$; b path = -0.38, $p < 0.001$, ab path = -0.34, CI = -0.64 to -0.04; based on 5,000 bootstrap samples, Model 4). When both mediators were entered together in a parallel mediation model, there was only a significant indirect effect of negligence (a path = -0.81, $p < 0.001$; b path = 0.63, $p < 0.001$, ab path = -0.51, CI = -0.77 to -0.28; based on 5,000 bootstrap samples, Model 4), and none for need for explanation (a path = -0.05, $p < 0.001$; b path = -0.06, $p = 0.086$, ab path = -0.05, CI = -0.12 to 0.01; based on 5,000 bootstrap samples, Model 4). Essentially the same pattern of results held when analyzing the island

and ship vignettes individually, the only exception being that there were significant

indirect effects of both negligence and need for explanation for the ship vignette (for full

results, see the Supplemental Materials).

Discussion

Overall, the results of Study 2 support the mentalistic account of the optimality bias

over the behaviorist account. Using two newly developed vignettes, we once again

replicated the optimality bias, showing that individuals were blamed for making

suboptimal choices, even though they apparently could not have known any better at the

time of their choice. Critically, however, we found that this bias was significantly amplified

among experts as compared with non-experts. The optimality bias (i.e., the blame

difference for suboptimal vs. optimal choices) was highly significant among experts, both

when aggregating both vignettes together, and when analyzing each individually. But this

effect was not significant among non-experts in the analysis that aggregated across

vignettes, and not significant for either vignette when analyzed singularly. What explains

this interaction? We surmise that the explanation fundamentally depends on mental state

and capacity inferences. In essence, experts are believed to have a greater capacity to

discern the correct path of action (even, apparently, when the lack of evidence renders that

a formidable task), and as a consequence of these superior capacities, they are held to a

higher epistemic standard than are non-experts. A purely behaviorist account, which

explains optimality bias solely in terms of the relative efficiencies of optimal and

suboptimal choices – that is, the mere fact that a suboptimal choice is suboptimal – cannot

explain why the bias should be amplified for experts.

Mediation evidence tended to favor negligence over need for explanation, especially in

joint mediation models, although both variables demonstrated significant indirect effects

when analyzed in isolation. Study 3a was designed to provide another experimental means

of testing the mentalist account of the optimality bias, and to provide further evidence on

417 potential mediating processes.
